<p align="center"><u>Project: Diamond Prices</u></p>

Step 1: Understanding the Model

1. According to the model, if a diamond is 1 carat heavier than another with the same cut, how much more should I expect to pay? Why?

   - The one additional carat would result in an additional $8,413 in price. The formula created by the regression determined that the coefficient for a carat is 8413, so for every increase in the number of carats the price will increase by the amount of the coefficient.

2. If you were interested in a 1.5 carat diamond with a **Very Good** cut (represented by a 3 in the model) and a **VS2** clarity rating (represented by a 5 in the model), how much would the model predict you should pay for it?
   - The formula is : **Price** = -5,269 + 8,413 x **Carat** + 158.1 x **Cut** + 454 x **Clarity**

     - so now we will plug in the values for the different variables.
     - **Price** = -5,269 + 8,413 x **1.5** + 158.1 x **3** + 454 x **5**
     - **Price** = 10,094.8 $

Step 2: Visualize the Data

1. Plot 1 - Plot the data for the diamonds in the database, with carat on the x-axis and price on the y-axis.
2. Plot 2 - Plot the data for the diamonds for which you are predicting prices with carat on the x-axis and predicted price on the y-axis.
   - **Note**: You can also plot both sets of data on the same chart in different colors.
3. What strikes you about this comparison? After seeing this plot, do you feel confident in the model's ability to predict prices?

Price vs Carat
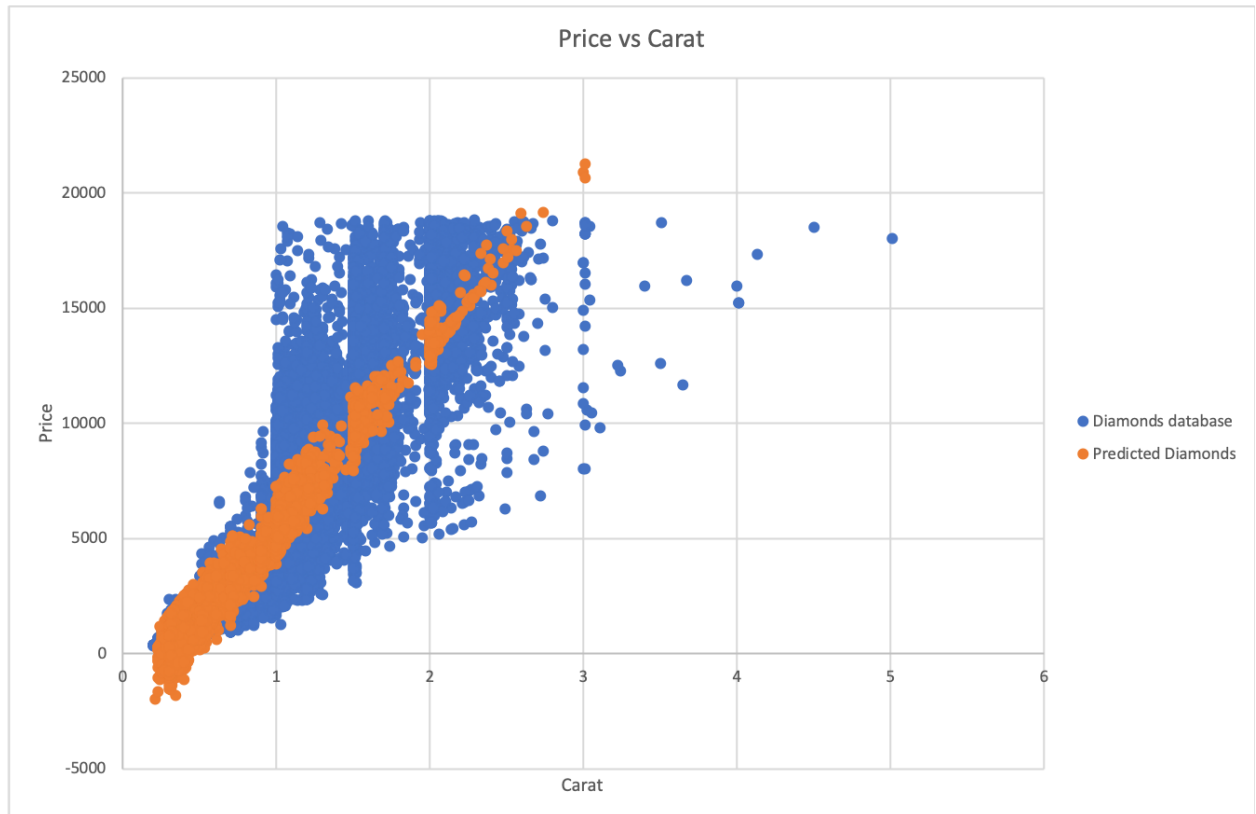

- The predicted prices have a high correlation than the actual data is. This is because we are not accounting for everything that effects prices. There are many more things than carat that may affect it. We had carat, cut and clarity factored in to our formula but not even that will account for all the variation. For instance, this formula might look very different depending on other factors like shape and color.

- After looking at this plot the model appears on average to predict the prices ok, but it can be very off for certain diamonds. There appears to be an outlier home with only 1 carat but sold for almost $18,000+. While the formula may not be accurate for an individual diamond, it should do a decent job at predicting the price we should pay for several diamonds at once since it on average looks representative.

Step 3: Make a Recommendation

1. What price do you recommend the jewelry company to bid? Please explain how you arrived at that number.

- I recommend a bid of $ 8,213,465.93. I arrived at this number by using a formula from the regression model provided that was based on previous diamonds sales and applied it to the diamonds that were up for bid. Since the company generally

purchases diamonds from distributors at 70% of that price, so I multiply the predicted amount $11,733,522.76 by 0.70 to get the final predicted bid of $8,213,465.93.
